Received: 5 March 2007 Returned for revision: 9 May 2007 Accepted: 11 July 2007

- **Background and aims** During the development of multicellular organisms, cells are capable of interacting with each other through a range of biological and physical mechanisms. A description of these networks of cell–cell interactions is essential for an understanding of how cellular activity is co-ordinated in regionalized functional entities such as tissues or organs. The difficulty of experimenting on living tissues has been a major limitation to describing such systems, and computer modelling appears particularly helpful to characterize the behaviour of multicellular systems. The experimental difficulties inherent to the multitude of parallel interactions that underlie cellular morphogenesis have led to the need for computer models.
- **Methods** A new generic model of plant cellular morphogenesis is described that expresses interactions amongst cellular entities explicitly: the plant is described as a multi-scale structure, and interactions between distinct entities is established through a topological neighbourhood. Tissues are represented as 2D biphasic systems where the cell wall responds to turgor pressure through a viscous yielding of the cell wall.
- **Key Results** This principle was used in the development of the CellModeller software, a generic tool dedicated to the analysis and modelling of plant morphogenesis. The system was applied to three contrasting study cases illustrating genetic, hormonal and mechanical factors involved in plant morphogenesis.
- **Conclusions** Plant morphogenesis is fundamentally a cellular process and the CellModeller software, through its underlying generic model, provides an advanced research tool to analyse coupled physical and biological morphogenetic mechanisms.

**Key words:** Pattern formation, dynamic model, CellModeller, multicellular systems, morphogenesis, cell–cell interaction.

### INTRODUCTION

In most living organisms, the cell constitutes the elementary structural and functional unit of life. Cells are capable of synthesizing new proteins, thereby maintaining a large variety of specific cellular activities which in turn encode complex developmental processes. Though plant organisms are complex, the position and shapes of cells, tissues, meristems and organs bear repeated and regular relationships with one another. The spatial organization and regularity of patterns are apparent not only at a macroscopic level, but also in meristems and tissues, which contain repeated and predictable arrangements of cells of various types.

Patterning in plants is highly organized and the mechanisms of interaction and communication between cells are central to an understanding how cell activity is co-ordinated during development. Primitive modes of chemical interaction appear in bacterial quorum sensing, e.g. where the density-dependent bioluminescence of *Vibrio fischeri* colonies is triggered by the perception of the AHL signalling molecules (Waters and Bassler, 2005). In higher plants, such mechanisms have evolved and morphogenesis is characterized by a large range of cell–cell signalling mechanisms. Diffusion of activating/inhibiting proteins is thought to be involved in the patterning of trichome differentiation (Glover, 2000; Schellmann and Hulskamp, 2005) and active polar transport of hormones is involved in the canalization and maintenance of growth in meristems (Benkova *et al.*, 2003; Friml, 2003; Scarpella *et al.*,

2006). These elaborate and co-ordinated behaviours underline the importance of studying intercellular communication and its role in the spatial and temporal co-ordination of cellular processes within plants.

Molecular genetics has provided great insight into the understanding of the nature of genetic interactions and their role in regulating cell development. However, genetic analysis is time consuming when the number of regulatory factors is large, and the use of computational techniques is becoming increasingly important for the identification of regulatory networks. Pioneering work by Turing (1952), further developed by Meinhardt (1994), has set a theoretical framework for pattern formation in biology. Since then, the use of computational methods for analysing development has grown considerably: image-analysis tools are being used to process microscopy images and quantify deformation in tissues (Dumais and Kwiatowaska, 2001; Barbier de Reuille *et al.*, 2005; Bengough *et al.*, 2006; Lee *et al.*, 2006); reaction diffusion models have been used to describe the co-ordination of cell behaviour (Furusawa and Kaneko, 2003; Jönsson *et al.*, 2006a); genetic regulatory networks have been used to model differentiation in the floral meristem (Espinosa-Soto *et al.*, 2004); and feedback-regulated models for polar flux of auxin introduced by Mitchison (1980) have been used to predict canalization in vascular tissues (Feugier *et al.*, 2005; Rolland-Lagan and Prusinkiewicz, 2005).

However, the computation of multicellular systems remains challenging in various aspects. The spatial and time scales involved in the biological processes are wide ranging from molecular to organismal phenomena.

\* For correspondence. E-mail lxd20@cam.ac.uk

Modelling studies and biological data that remain have not been integrated into life-like multicellular plant systems. This study presents a new general model of cellular morphogenesis, based on a multi-scale description of cell architectures and molecular interactions. The model has been implemented in CellModeller, a system dedicated to multicellular computations. Three examples are developed to illustrate genetical, hormonal and mechanical patterning mechanisms.

## GENERAL MORPHOGENETIC MODEL

### Multi-scale spatial structure

Botanists have long recognized that plants are organized into units of various types and sizes, e.g. cells, tissues, organs, where mutual interactions explain a multitude of regulatory mechanisms (Sachs, 1991). Describing the architecture of relationships amongst the plant constituents is a crucial step prior to modelling interactions within those units. This can be formalized by defining the plant as a set of scales of description  $s \leq S$ , where each entity within a given scale of description is of the same type (represented in parallel plane in Fig. 1). For example, walls are the entities described at scale 1 characterized by their properties ( $W_i$ ), cells are objects described at scale 2 characterized by ( $C_i$ ), and tissues are described at scale 3 characterized by ( $TI_i$ ).

Because entities at different scales of description encapsulate different representations of the same plant, hierarchical relationships can be defined between these different structural entities: cells are made of walls, tissues are made of cells, etc. . . . These relationships are defined through incident or ‘vertical’ functions (Fig. 1A), denoted  $v^-$  and  $v^+$ , which describe the hierarchy of entities at different scales of description. The function  $v^-$  assigns to a given entity of level  $s$ , e.g. an epidermal cell, the set of incident entities at level  $s - 1$ , e.g. the set of walls that define the cell boundaries.  $v^+$  is the function which assigns a given entity at scale  $s$ , the entity to which it belongs to at scale  $s + 1$ , e.g. the epidermis. For example, the set of walls that constitutes the boundaries of the  $i$ th cell can be written as  $W_{v^-i}$ .

Certain factors that regulate cell behaviour in plants can be transported from cell to cell, e.g. hormones, transcription factors and secreted peptides. These signalling processes play an important role in the co-ordination of plant cell development and provide key positional information determining cell patterning and differentiation. Therefore, interactions between units of the same level need to be defined in order to complement the previous topological structure. Neighbouring relationships will be referred to as ‘horizontal’ in contrast to the previous definitions. The partition between two cells is double-walled, with each cell’s wall having an independent composition, architecture and properties.  $W_{hi}$  is therefore the neighbouring wall in contact with the  $i$ th wall. The neighbouring function can then be extended to higher levels of description by recurrence.

### Dynamics of cellular properties

The previous section described a static network of connections ( $v^+$ ,  $v^-$ ,  $h$ ) between a set of independent cellular objects characterized by their biological/physical properties, e.g. turgor pressure, concentration of transcription factors in a cell. However, plant functioning is highly dynamic, and even stationary patterns may result from motion and interaction of signalling molecules within the organism (Meinhardt, 1994).

Therefore, in this section, the dynamics of the cellular properties, e.g.  $W_i$  and  $C_i$ , are defined within the architecture of cells. The evolution of such variables with time cannot be encapsulated in isolated autonomous factors, but is influenced by the properties of other plant constituents. In real plant systems, processes of interaction such as diffusion of morphogens between adjacent cells/tissues, result from the proximity of cellular entities and can be expressed in models via a topological ‘neighbourhood’ defined by the functions  $v^+$ ,  $v^-$ ,  $h$  (Fig. 1C). For  $1 < s < S$ , one such model may be defined as:

$$\partial C_i / \partial t = P + J + F^+ + F^- \quad (1)$$

The first component  $P$  of the right-hand side is the cell internal production term:

$$P = p(C_i, t) \quad (1A)$$

$P$  expresses the rate of synthesis of the molecules at a cell level and the function  $p$  may encode complex gene regulatory networks and other biochemical dynamics. The second term  $J$  denotes the horizontal interactions between entities of the same types, e.g. transport of molecules between cells. The net influx  $J$  entering a particular entity can be broken down into individual contributions at each interface between elements  $i$  and  $hi$  at scale  $s - 1$ :

$$J = f(W_{hi}, C_{v^+hi}, t) - f(W_{hi}, C_{v^-i}, t) \quad (1B)$$

The flux from  $i$  to  $hi$  is therefore opposite to from  $hi$  to  $i$ , which is coherent with the conservation of quantities within the whole system.  $f$  may express simple diffusion, in which case  $f$  is expressed as  $D \cdot C_{v^+i}$ , or other types of molecular transport (Vieten *et al.*, 2007).  $F^+$  represents the influence of processes from scale  $s + 1$  and  $F^-$  the integrated influence of entities at a lower scale:

$$\begin{aligned} F^+ &= f^+(TI_{v^+i}, t) \\ F^- &= \sum_{j \in v^-i} f^-(W_j, t) \end{aligned} \quad (1C)$$

Similar equations can be written for each entity of the system. When  $s = 1$ , there is no influence from the lower scale and both  $J$  and  $F^-$  are set to 0. Similarly when  $s = S$ , no influence from the higher scale is defined and  $F^+$  is set to 0.

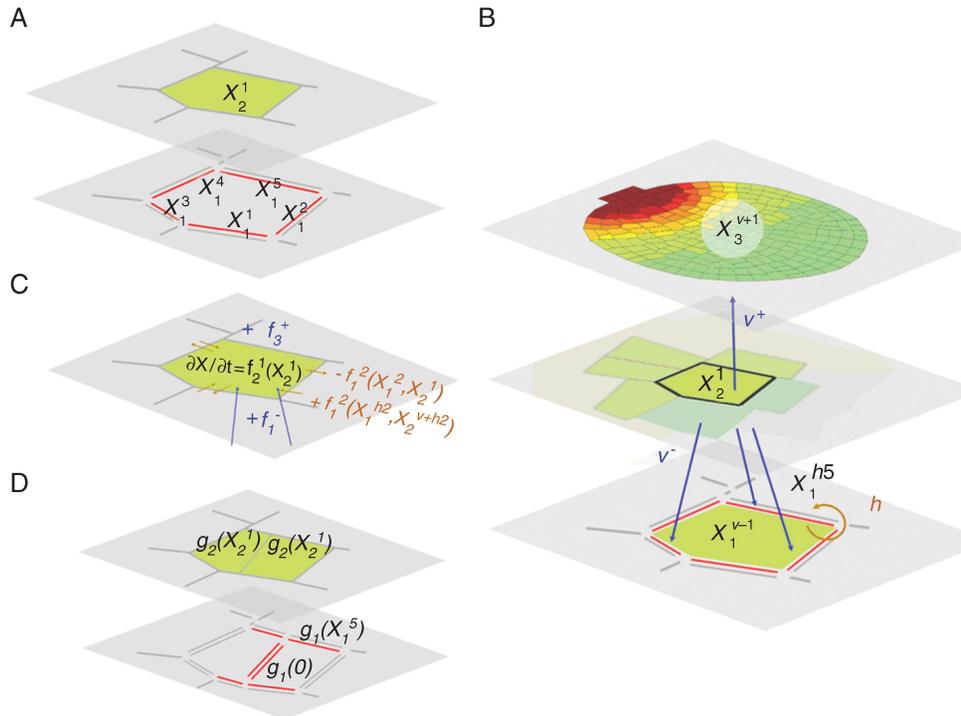

FIG. 1. (A) Plant cellular architecture can be broken down into entities at different scales, represented here on horizontal planes to describe plant structure and functioning. (B) The entities in each level of description establish interactions with other plant constituents, and it is possible to determine a topological neighbourhood for any entity: a cell is related to its neighbours according to  $h$ , but also within the organ it belongs to via  $v^+$  and the walls that define its boundaries via  $v^-$ . (C) The evolution of such properties is relevant to autonomous processes, e.g.  $f_2^1$  function in cell  $X_2^1$ , but is also due to interactions between entities in the topological neighbourhood, e.g. via  $f_3^+$ ,  $f_1^-$  and  $f_2^2$  functions. (D) Changes in the network of interactions are due to growth mechanisms and can be broken down into birth and death operators: the division of the cell  $X_2^1$  results from the deletion of four walls, i.e.  $X_1^1, X_1^{h1}, X_1^5, X_1^{h5}$ , and the creation of ten new walls (eight subdivision from previous walls plus the two new walls separating the newly created cell). Entities associated with new walls are then defined through the inheritance function  $g_1$  and those associated with the two daughter cells through  $g_2$ .

### Architectural dynamics

The changes induced by growth and cell proliferation mechanisms to the architecture of plant components must be considered. The dynamic systems outlined in the previous section described the evolution of the cellular properties in a fixed layout of cells which is equivalent to cellular development in the absence of cell proliferation.

Any change in the architecture of the system, inherent to events such as cell division or cell death, can be expressed as a combination of elementary creation and deletion operators at different scales of description. The deletion of an entity from the plant structure implies only the suppression of connections within the topology. Creation of an entity requires additionally the initiation of the new object properties  $C_d$  (Fig. 1D). At the time of creation, this will be defined through the inheritance function  $g$  so that:

$$C_d = g(C_i) \quad (2)$$

$g$  may encode important biological concepts such as asymmetric division, lineage and other mitotic events. For example, the partitioning of a single cell  $C_1$  into two equal daughter cells  $C_{d1}$  and  $C_{d2}$  can be modelled by a simple  $g$  function:  $C_{d1} = C_{d2} = C_1/2$ . After such an event,

continuous dynamics resume with a new set of initial conditions and connectivity.

### Biomechanics of growth

Plant cell expansion is generally believed to result from the yielding of cell walls maintained under tension by turgor pressure, and both of these factors are ultimately controlled by the plant genetic activity (Fig. 2). Experimental evidence from observations of the ultrastructure of cell walls (Taiz, 1984) and from observed expansion rates after imposition of shifts in turgor (Green *et al.*, 1971) favours inelastic models for wall expansion. Here a quantitative model for cell wall physics has been incorporated by adopting a pure viscous model to relate turgor pressure to cell wall properties. A simple viscous model has the advantage of being described by a single parameter, the viscosity coefficient, which has a strong physical meaning and can be easily estimated from experimental work. A finite element beam model (Euler Bernoulli assumptions) has been adopted. At each increment in time, a forward-Euler finite difference scheme was applied to derive nodal displacement. The forces present within cell walls are determined *a posteriori* from nodal displacements using the viscous strain/stress relationships. A fuller description of the

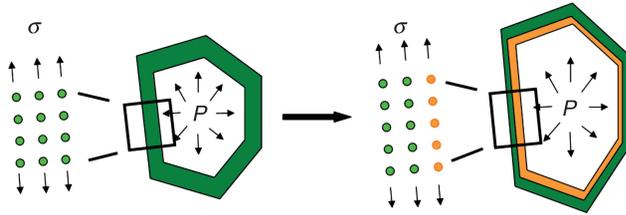

FIG. 2. Biomechanical model for cell expansion in morphogenesis: cell wall response to turgor pressure through a viscous yielding of the cell wall, compensated at the same time by thickening to maintain a constant cross-section.

biomechanical model can be found in a previous publication (Dupuy *et al.*, 2006).

#### *CellModeller, modelling system for multicellular computation*

CellModeller, software environment for 2D multicellular computations, has been developed. The system was developed in C++ and is based on a hierarchical data structure representing the network of interactions described in previous sections. Plant object classes contain the cellular properties, such as spatial co-ordinates for the vertex class, and also corresponding references to other entities that build up the topology of the system, i.e. functions  $v^+$ ,  $v^-$  and  $h$ . Member functions provide elementary geometrical tools (areas, normal vectors, axes of inertia), topological operators triggering architectural events (divide, ablate, neighbouring), and also built-in models (mechanical model, diffusion of morphogens).

The dynamic system presented in eqn (1) breaks down the interactions between plant entities as a linear combination of terms from entities at different scales, i.e.  $F^-$ ,  $P + J$  and, respectively,  $F^+$ . This decomposition is convenient from a computational point of view, because the evolution functions  $f_s$  in eqn (1) can be constructed iteratively by running through all the plant compartments once in a time step. In CellModeller, such evolution functions can be coded in scripts specific to a scale of description and operating on the C++ data structure. Two types of scripts (Fig. 3) are associated at each level of description. ‘Regular’ scripts are called at each time step of the simulation and encode user-defined evolution functions  $p$ ,  $f$ , but can also trigger topological changes by making use of divide or ablate functions (Fig. 2). ‘Init’ scripts are called when a new object is created, e.g. functions  $g$  in eqn (2), to specify inheritance rules.

Scripts consist of user-defined functions that operate on the C++ cellular objects through a python interface. This architecture gives the users control of the topological data structure and, at the same time, provides a powerful and user friendly scripting language for designing models and extending the functions of CellModeller. CellModeller can also be used for the extraction and reconstruction of real cellular architectures by image analysis, for carrying out statistical analysis on cell architectures, and for visualization. More information can be found on the web site <http://www.plantsci.cam.ac.uk/Haseloff/CellModeller2/index.html>.

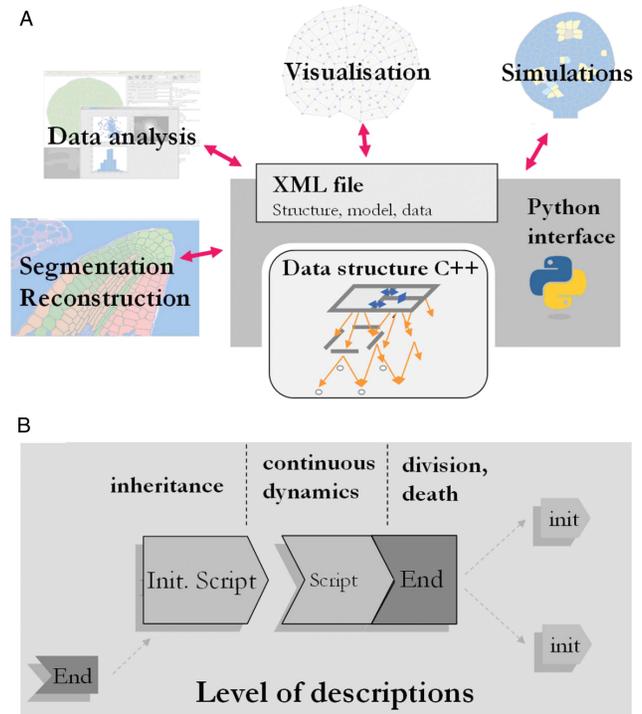

FIG. 3. (A) In the CellModeller software, a C++ chained data structure was developed in order to define explicitly the topological neighbourhood of any entity. This data structure is wrapped in a Python interface and can be used for various types of applications (extraction and reconstruction of real cellular architectures, statistical analyses, visualization and simulations). (B) Models can therefore be programmed by an association of self-contained scripts, operating on a type of entity and containing a description of both autonomous processes and interactions within the architecture. For any level of description, one script is used to define inheritance rules (function  $g_s$ ), and the second script encodes the continuous dynamics of attributes (function  $f_s$ ). The latter script also controls proliferation rules (division and death) and triggers architectural changes in the system.

#### APPLICATION TO THREE STUDY SYSTEMS

In this section, the concepts developed previously are applied to three different types of patterning mechanisms, namely genetic regulation, hormonal signalling and mechanical interactions. These applications involve three levels of plant description: the wall level  $W$ , the cell level  $C$ , and the tissue level  $TI$ , for which the indexing of their respective entities will be omitted to simplify the notations.

##### *Case 1: genetic regulation in the trichome patterning system*

During leaf development, the differentiation of epidermal cells into trichomes (leaf hairs) occurs in precise patterns and frequencies. Recent work on the arabidopsis trichome system has identified the role of various genes involved in the regulation of trichome patterning (Schellmann and Hulskamp, 2005). *GL1* (*GLABRA1*) and *TTG1* (*TRANSPARENT TESTA GLABRA1*) are two transcription factors required for the formation of trichomes. *GL3* is a positive regulator of trichome fate which associates with *GL1* and *TTG1* to form a complex that activates genes

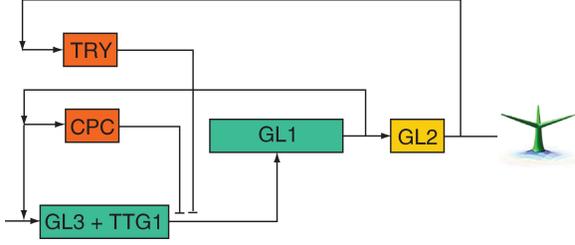

FIG. 4. The generation of the spacing patterns of trichomes in Arabidopsis, results from a group of activators (in green) and inhibitors (in red). GL3 is a positive regulator of trichomes which associate with GL1 and TTG1 to form a complex that activates the trichome developmental genes which are reduced here to the single *GL2* gene. In trichome cells, levels of the inhibitors increase and diffuse into neighbouring cells, where they block the activity of the activating complex, and in turn the trichome fate.

associated with trichome fate (Pesch and Hulskamp, 2004) which is reduced here to the single *GL2* gene. The lateral movement of inhibitors regulates the activity of this complex. In non-trichome cells, the inhibiting proteins TRY (*TRIPTYCHON*) and CPC (*CAPRICE*) compete with GL1 and an inactive complex is formed (TRY or CPC/GL3/TTG1) (Schellmann *et al.*, 2002).

In this example, a simplified plausible regulatory network has been studied (Fig. 4), representing interactions between these regulatory genes. The evolution of the concentration of the different gene products ( $C_{GL3}$ ,  $C_{TRY}$ ,  $C_{CPC}$ ,  $C_{GL2}$ ) is defined by classical rate equations (Jönsson *et al.*, 2006a; Smith *et al.*, 2006), driven by an internal production rate, a degradation coefficient and an influx term:

$$\frac{\partial C}{\partial t} = P - \lambda C + \sum_{i \in \mathcal{V}^-} J_i \quad (3)$$

$P$  is the production rate,  $\lambda$  the decay constant and these first two terms constitute the net production term defined in eqn (1).  $J_i$  is the net influx from wall  $i$  and encodes the  $f$  function as seen in eqn (1). The production terms of the different gene products encapsulate the interactions between the different genes shown in Fig. 4 as follows:

$$\begin{aligned} P_{GL3} &= \frac{\mu_{GL3}}{C_{CPC}} \cdot \frac{C_{GL3}^2}{1 + C_{GL3}^2} \cdot A_{GL3}(C_{TRY}, C_{GL2}) \\ P_{CPC} &= \mu_{CPC} C_{GL3}^2 + C_{CPC} \\ P_{TRY} &= \mu_{TRY} A_{TRY}(C_{GL2}) \\ P_{GL2} &= \mu_{GL2} A_{GL2}(C_{GL3}) \end{aligned} \quad (4)$$

In this reduced genetic regulatory network, GL1 and TTG1 are always present and no rate equation is defined: the concentration of GL3 in the cell determines directly the formation of the positive-reinforcing complex GL1/TTG1/GL3 which in turn activates GL2. The regulation of GL3 is the result of the interactions between TRY and CPC. GL3 and CPC are the classical activator inhibitor couple defined by Meinhardt (1994; its application to the

trichome patterning system was also carried out by Benitez *et al.*, 2007) and these act upstream of GL2. The second inhibitor TRY is activated downstream of GL2, as indicated in experimental studies (Srinivas, 2004). Once a trichome is initiated in a cell, it represses trichome formation in neighbouring cells.

Activation of genes is expressed through a combination of elementary sigmoid threshold functions:

$$A(X) = 1/[1 + \exp(-d(X - m))] \quad (5)$$

where  $m$  indicates the level of input under which the entity is not active, and  $d$  denotes the sharpness of the transition ( $d$  is given a large value to obtain clear on/off activation states). The activation function  $A_{GL3}$  encodes the inhibition of TRY on GL3 and the irreversibility of the trichome developmental process (repression is inefficient if GL2 has been activated). In this case, the activation function equals  $A = 1 - A_i(X)A_j(-Y)$  (see Table 1 for the parameter values).

Gene product can diffuse between cells. The net influx  $J$  going through the wall  $i$  of length  $l$  with a diffusion coefficient  $D$  therefore equals

$$J = Dl(C_h - C) \quad (6)$$

Initial conditions for the simulations consisted of three cells immobilized and three active cells on the top of them, where the genetic script operates. Cells are initiated with a small amount of GL1 (random uniform distribution [0, 0.05]). A degree of noise was introduced at division to prevent identical neighbour cells. Focusing on the adaxial surface of the leaf, a plane layout of cells was represented. Trichome formation is inhibited on edge cells in order to avoid modelling the remaining epidermal cells.

The execution of this model reproduced the expected patterns of gene expression seen during trichome development (Fig. 5). When GL3 in the cell increases significantly by depletion of CPC inhibitor, GL2 is expressed and a trichome is initiated. TRY and CPC are both generated at the site of trichome development and diffuse to inhibit laterally the emergence of new trichomes in the neighbourhood. Most importantly, this model could be mutated and the phenotypes of virtual mutants analysed (Fig. 6). The *cpc* mutant showed an increase in trichome density as observed experimentally (Schellmann *et al.*, 2002). The *try* virtual mutants had clusters of trichomes. Real *try* phenotypes also generate clusters of trichomes (Schnittger *et al.*, 1998), although generally made of two cells in real

TABLE 1. Parameters of the model for the trichome patterning system

	$\mu$	$c$	$\lambda$	$D$	$m_i$ (*)	$m_j$ (*)

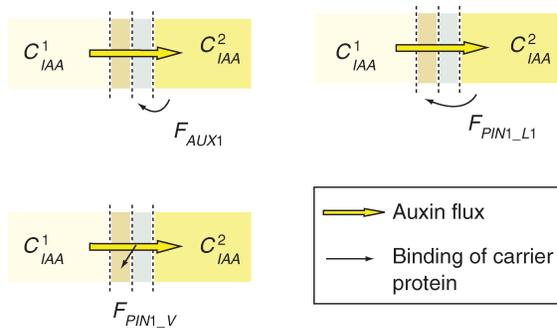

FIG. 7. In the primordia, influx and efflux carriers are thought to direct auxin flows and maintain regions of higher concentrations. The localization of the carrier molecules that maintain such patterns are inherent to feedbacks with the levels of auxin concentration and fluxes in cells. In AUX1 transport, the feedback  $F$  is inherent to the concentration of auxin in the cell. In PIN1 in the L1 layer, the rate of allocation is positively correlated with the concentration of auxin in the neighbouring cell. The canalization of the flux of auxin by PIN1 deeper in the tissue is induced by the flux of auxin through the cell wall.

*et al.* (2003) and Vieten *et al.* (2007). The canalization of fluxes (Sachs, 1991) in sub-epidermal layers of cells does not seem to respond to the same feedback rules as those observed in epidermal cells driving fluxes to converge towards leaf primordia. To date there are no molecular models or data explaining this behaviour. Therefore it was assumed for simplicity that the model of PIN1 allocation is tissue specific. The allocation of the *PIN1* carrier in the L1 layer is reinforced by the concentration in the neighbouring cell  $F_{PIN\_L1} = IAA_h$  (Barbier de Reuille *et al.*, 2006; Jönsson *et al.*, 2006b). The localization of PIN1 in deeper tissues is reinforced by a positive feedback with auxin flux:  $F_{PIN\_V} = J_{IAA}$ . Readers may refer to Feugier *et al.* (2005) or Rolland-Lagan *et al.* (2005) for a more complete overview of auxin canalization models.

Once attached to cell wall membranes, a carrier molecule has the ability to convey auxin against a gradient of concentration. Classically, this is expressed in specific transport equations, for each carrier molecule  $W$  associated to a wall of length  $l$ :

$$J_{IAA} = Tl[(W_h \times IAA_h) - (W \times IAA)] \quad (10)$$

where  $J_{IAA}$  is the contribution to the total flux of auxin due to a given influx carrier  $W$ .  $T$  is a constant transport coefficient specific to the carrier molecule. In the case of efflux transport, the relationship is inverted.

High auxin concentration induces high rates of cell expansion (deformation remains slow with comparison to biochemical aspect though). A simple empirical relationship between the wall viscosity coefficient and the auxin concentration was used:

$$\text{viscosity} = 1 + 30A_{\text{viscosity}}(-IAA) \quad (11)$$

The initial conditions for the simulations consisted of a brick of  $11 \times 3$  cells. The vertical displacement of the bottom/top faces and all the displacements of the interior

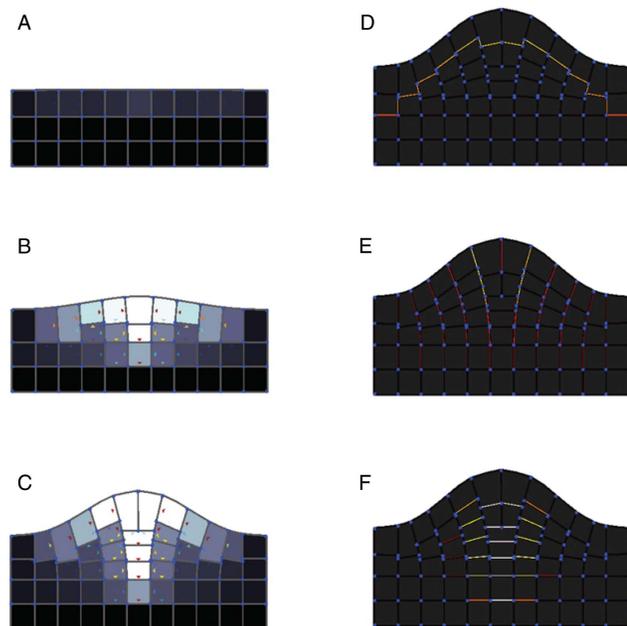

FIG. 8. Establishment of the ‘reverse fountain’ cycling of auxin: (A) initial conditions, (B) direction of flux towards the local maxima of auxin concentration; (C) redirection and canalization of the flux towards deeper tissues. The transport of auxin is mediated by carrier molecules distributed heterogeneously on cell walls: (D) AUX1 influx carrier conveys auxin to the L1 layer, (E) PIN1 efflux carrier directs the flux towards the site of maximum concentration in the L1 layer, (F) canalization process by PIN1 in deeper cells redirects the flux downwards (see Supplementary Information Video ‘Fountain’ available online).

cells and left face were fixed. To initiate the converging flow of auxin on the middle cell, PIN1 is initiated symmetrically around the horizontal axis on the L1 layer.

The model was used to analyse the resulting patterns of auxin flows and concentration. During the simulation, a transient phase was observed during which flows of auxin were progressively conveyed towards the central epidermal cell where a peak of auxin concentration was formed as described by Heisler *et al.* (2005). The flux is then redirected downward due to the positive feedback between PIN1 and auxin flux in sub-epidermal cells, as observed during the emergence of leaf primordia (Reinhardt *et al.*, 2003). The nature of the feedback between auxin concentration and carrier allocation (eqn 9) reinforced and maintained this circulation in a quasi steady state. At this stage, the model also reproduced the schemes of PIN1 and AUX1 distribution observed at the early stage of young primordia. (Fig. 8). Simulations took 4 min for structures of up to 70 cells, 280 walls and for a total of 2000 time increments using user-specific Python functions for wall and cell entities.

### Case 3: mechanical interactions in the formation of an outgrowth

Further, cell–cell mechanical interactions were chosen for illustration by simulating a simple case of an outgrowth. In the shoot apical meristem, for example, initiations of primordia are accompanied by cell proliferation under the

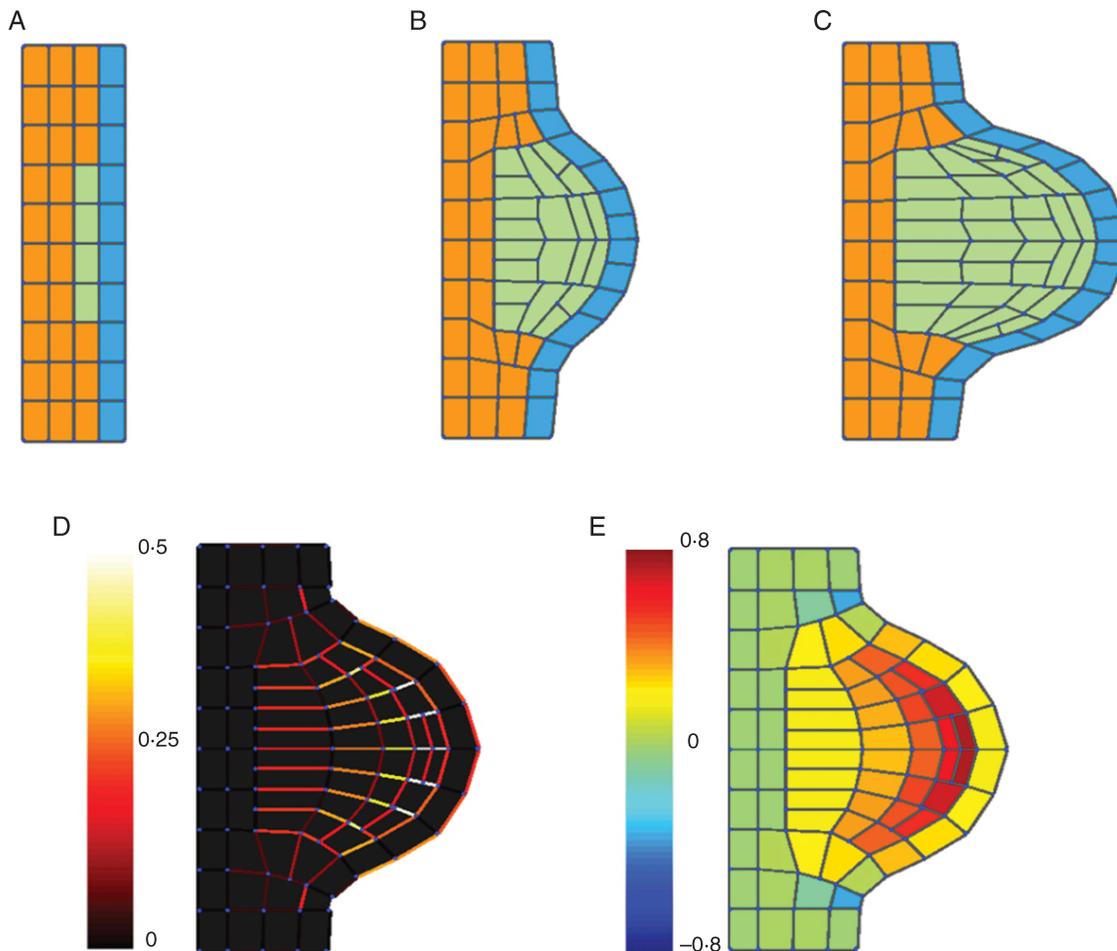

FIG. 9. The influence of mechanical interactions and tissue morphogenesis was illustrated by the simulation of an outgrowth generated by three tissues expanding at different rates. A fast-growing tissue (green) is adherent to two slowly growing surrounding tissues (blue, orange): (A–C) different stages of the development of the outgrowth; (D) strain rate distribution in cell walls ( $10^{-1} \text{ h}^{-1}$ ); (E) areal strain rate ( $10^{-1} \text{ h}^{-1}$ ) (see Supplementary Information Video ‘Outgrowth’ available online).

L1 layer in which the primordia are initiated. Expanding cells remain largely adherent to surrounding tissues, and the mechanical behaviour of all tissues influences the kinematics of expansion in the emerging meristem.

According to Selker *et al.* (1992), a possible way for the meristem to develop a localized bulge is for a localized pressure and/or a wall to soften the epidermal cells in which the primordia are initiated. This was modelled by a simple architecture of cells consisting of three different tissues: the first tissue constituted one layer of cells and represented the L1 layer (blue in Fig. 9). The second tissue was composed of three layers of cells under the L1 layer (orange). At the beginning of the simulation, four cells of the second tissue enter a proliferation stage (third tissue in green). The wall properties (viscosities and moment of inertia) are set at the level of the tissue:

$$W = TI_{(v+)^2} \quad (12)$$

The properties of each tissue ( $TI$ ) are constant with time. The proliferating cells have the same turgor pressure and

radial expansion of walls is due to 50–100 times lower viscosity of cell walls. All cells have the same wall viscosities in the radial direction (Table 3). Cell type and therefore wall properties are inherited at division.

The model predicted an increase in tensile stresses in the epidermis as it is observed generally at the surface of meristems (Dumais and Steele, 2000). Small regions of compression stresses were generated on the sides of the outgrowth and these are consistent with experimental

TABLE 3. Mechanical parameters of the mechanical model of interacting tissues

	Viscosity ( $\text{GPa s}^{-1}$ )	Moment of inertia ( $\mu\text{m}^4$ )	Pressure (MPa)
L1 – long axis	$1 \cdot 10^4$	$5 \cdot 10^1$	1
L1 – short axis	$1 \cdot 10^6$	$5 \cdot 10^2$	1
Proliferating	$1 \cdot 10^4$	$5 \cdot 10^0$	1
Interior – long axis	$1 \cdot 10^4$	$5 \cdot 10^1$	1
Interior – short axis	$5 \cdot 10^5$	$5 \cdot 10^1$	1

observations by Kwiatkowska and Dumais (2003). The mapping of the cell's deformation state (volumetric strain and principal strain rate components; cf. Fig. 9), indicated limited correlations between tissue type and expansion rate. The overall behaviour of the model observed during the simulations showed gradual deformations taking place across the different tissues. These deformations are driven by the proliferating cells of the third tissues, but mechanical forces are propagated to neighbouring cells through the extracellular matrix continuum. Calculation time was about 50 s for 450 time steps, 90 cells and 400 walls.

## DISCUSSION

### *Improved multicellular computational systems*

Considerable progress has been made in the modelling of multicellular genetic systems, and different computational tools have been developed in the plant scientific community. Continuous representation of tissues has been employed to investigate patterning mechanisms in static contexts and these were applied notably to the trichome regulatory system and the canalization of auxin in the leaf (Fujita and Mochizuki, 2006; Benitez *et al.*, 2007). These simulation schemes can easily be programmed using standard numerical packages, but remain limited when dealing with growth and cellularity. Models with explicit descriptions of cells have been developed recently and applied to the root (Chavarria-Krauser and Schurr, 2004; Swarup *et al.*, 2005) and the shoot apical meristem (Barbier de Reuille *et al.*, 2006; Jönsson *et al.*, 2006b; Smith *et al.*, 2006). Cell growth has been represented using repulsive spring forces between the centres of neighbouring cells and these systems could be applied to predict the placing of primordia in different phyllotactic patterns (Jönsson *et al.*, 2006b).

To date, however, most of these modelling tools have been designed for the analysis of specific experimental systems (SAM/RAM). A popular approach, also developed in animal sciences, is based on the Cellular Potts Models (Merks and Glazier, 2005). These systems cannot be ported into other fields of application without a significant investment in software development. Also, the description of growth kinematics is heavily limited due to the simplification of the physics of wall expansion and cell–cell mechanical interactions. The CellModeller system presented in this paper has overcome some of these shortcomings in several ways.

- (a) CellModeller is a generic system that addresses inter-cellular plant dynamics (no sub-cellular resolution). Cell populations of over 1000 cells can be simulated on a standard PC machine, and larger systems can be analysed with the sacrifice of interactivity and if new algorithms are used to take advantage of the parallel and multi-scale functioning of plant systems.
- (b) Scripts are used to encode the behaviour of any type of entity within the system. This is a modular approach to the programming of cellular dynamics, and this facilitates the reuse of parts of an existing model.
- (c) The system provides a formal description of the architecture of interactions within the plant structure. Based on the network of connections between the entities of the architecture, it is possible to encode models with a large variety of patterning mechanisms and save them in XML file format.
- (d) CellModeller provides a finer description of the spatial structure, and incorporates a more precise biophysical model. The mechanics of cell–cell interaction are specific to plant systems: tissues are represented as 2D biphasic objects where a fluid (represented by the turgor pressure in each cell), interacts with the closed network of deformable cell walls.

### *Future prospects for plant morphogenesis*

Plant form arises from the multitude of genetic and physical interactions that occur within a growing assembly of cells. Although molecular techniques are now providing large amounts of information about the behaviour of cells and their functioning, still little is known about how those processes integrate within whole plant tissues and organs. Genetic analysis is time consuming when the number of interacting factors is large and it is becoming extremely complicated to identify the networks underlying the regulation of cell activity. Although the models were based on qualitative data from biological experiments, they have emphasized how computer models can provide essential information for understanding the functioning of cell–cell co-ordination during cellular morphogenesis.

Differentiation, an intrinsically cell autonomous process, was illustrated by the simple and well-characterized trichome genetic system (Guimil and Dunand, 2006). The simulation of the regulatory network predicting the trichome initiation sites have demonstrated the efficiency of numerical simulations to analyse different networks and help to test probable biological hypotheses. A simple regulatory network made of only two different types of inhibitors produced a range of plausible phenotypes, i.e. no clustering and regular spacing of initiation sites. Also, it was seen that variations in the topology of the network induced drastic changes in phenotypes, i.e. modification of density and appearance of clusters. Hormonal signalling also plays a central role in the regulation of local cell proliferation and cell differentiation (Fleming, 2006). The model of auxin polar transport showed that the dynamic allocation of carrier molecules is sufficient to maintain the gradients of hormone concentration in the primordia (Benkova *et al.*, 2003). Finally, growth and form in plants are intimately related to the regulation of the cell physical properties (Cosgrove, 2001). However, measuring the action of genes on the cell physical properties is particularly difficult within the 3D architecture of higher plants, and numerical mechanical analysis can be particularly helpful for investigating the behaviour of such composite structures.

Cell-based simulation approaches are becoming crucial tools for understanding the genetic regulation of plant development, and it is critical in the future that

computational systems allow for the analysis of the plant as a system rather than as separate components. The development of the CellModeller software, which facilitates the construction of morphogenetic models on different types of cellular entities, is a step towards more adaptive genetic/physical simulation systems for studying plant morphogenesis.

#### SUPPLEMENTARY INFORMATION

Supplementary Information is available online at <http://aob.oxfordjournals.org/> and consists of four QuickTime Movie videos showing short animations of the illustrations presented in Figs 5, 6, 8 and 9.

#### ACKNOWLEDGEMENTS

This research was supported jointly by the Biotechnology and Biological Sciences Research Council and Engineering and Physical Sciences Research Council research grant (BBS/B/16720, BEP/17053).
